Role of aggregated Fe oxo species in N₂O decomposition over Fe/ZSM-5

Bo Zhang, Fudong Liu, Hong He *, Li Xue

Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China

ABSTRACT

The effects of aggregated Fe oxo (FeOₓ) species on N₂O decomposition activity of aqueous ion-exchanged Fe/ZSM-5 were investigated. Aggregation of FeOₓ species was achieved by thermal treatment of the Fe/ZSM-5 catalysts at different temperatures (600–900 °C) in pure Ar. The characterizations were carried out using X-ray diffraction, N₂ physisorption, UV-Vis diffuse reflectance spectroscopy, X-ray absorption fine structure spectroscopy, pulse-response analysis, and O₂-temperature-programmed desorption. The FeOₓ species on the external framework of the ZMS-5 zeolite played a dominant role in N₂O decomposition over Fe/ZSM-5. By studying the relationship between the contents of the various existing iron species and activity of the different catalysts, polynuclear FeOₓ appeared to be the main active phase for N₂O decomposition. Additionally, Fe–O with a long bond length ((Fe–O)₂) in amorphous polynuclear FeOₓ was positively correlated to the activity of the catalysts, indicating that (Fe–O)₂ was the active species for N₂O decomposition.

1. Introduction

Nitrous oxide (N₂O) is a greenhouse gas and major stratospheric source of NO, contributing to ozone destruction [1,2]. Although N₂O is not a major contributor to global warming (~6%), its effect is much more potent than that of CO₂ and CH₄. Anthropogenic practices have led to a rapid increase in atmospheric N₂O concentrations, with an annual growth rate of 0.2%–0.3% [1]. Therefore, control of N₂O emissions from combustion and chemical processes has become a significant concern.

To control N₂O emissions from chemical processes, catalysts for N₂O decomposition have been widely studied in the last three decades. Among them, Fe/ZSM-5 [3–9] has been extensively studied owing to its remarkable activity and stability for N₂O decomposition even in the presence of relatively large amounts of O₂, NO, SO₂, and H₂O that are typical poisoning gases for other N₂O abatement catalysts. Fe/ZSM-5 has been traditionally prepared by aqueous ion exchange, solid-state ion exchange, and isomorphously substituted methods. Steaming [10–14] and thermal treatments [15–19] are beneficial for solid-state ion-exchanged and isomorphously substituted Fe/ZSM-5 for N₂O decomposition, and this has led to systematic investigations on the effect of steaming conditions on isomorphously substituted Fe/ZSM-5 [20–23]. Such research studies reported the key role of oligonuclear Fe oxo clusters or small intra-zeolitic Fe species on the external framework of the zeolite in N₂O decomposition, whereas Lewis and Brönsted acidic sites only play a minor role. Kačič et al. [24] reported that both the short Fe–Fe distances and the presence of

2.2. the MFI zeolite structure was retained after the thermally treated catalysts are referred to as FZT (where T is the temperature range of 600–900 °C in Ar). The resulting N2O decomposition activity of Fe/ZSM-5 treatments on N2O-decomposition activity remains controversial.

Because of its convenient synthesis, aqueous ion-exchanged Fe/ZSM-5 has been considered one of the most promising candidates for the decomposition of N2O emitted from industries. Certain types of iron species, such as iron ions and iron oxyhydroxide species, are prone to exchange with protons of zeolites. Moreover, (FeO)2-Al on the external framework can form in channels following calcination of Fe/ZSM-5 [25–27]. Previous research studies reported on the performance optimization of aqueous ion-exchanged Fe/ZSM-5 using varying solutions and iron sources [25,27]. The effect of thermal treatment on solid-state iron-exchanged and isomorphously substituted Fe-ZSM-5 has been studied by Pérez-Ramirez and Hensen et al. However, the influence of thermal treatment on aqueous ion-exchanged Fe/ZSM-5 relating to N2O decomposition activity is not well understood.

Herein, Fe/ZSM-5 catalysts were thermally treated in the temperature range of 600 to 900 °C in Ar. The effects of thermal treatment on the structure of Fe oxo species and textural properties of Fe/ZSM-5 were considered and characterizations were performed accordingly. To achieve varying types of iron species during thermal treatment, Fe/ZSM-5 with 2.6 wt% Fe (Fe/Al molar ratio = 1) was prepared by the aqueous ion-exchange method.

2. Experimental

2.1. Catalyst preparation

Fe/ZSM-5 catalysts were prepared by ion-exchange from aqueous solution. Briefly, HZSM-5 zeolite, with Si/Al molar ratio = 36, was added to Fe(III) nitrate aqueous solution at 90 °C. After vigorous stirring, the sample was washed and dried in air at 100 °C for one night (referred to as non-calcined Fe/ZSM-5). The non-calcined Fe/ZSM-5 was then calcined at 550 °C in air for 3 h (referred to as Original). Fe/ZSM-5 prepared with 2.6 wt% Fe (Fe/Al molar ratio = 1) was treated in the temperature range of 600–900 °C in pure Ar. The resulting thermally treated catalysts are referred to as FZT (where T refers to the temperature employed). X-ray diffractometry measurements of the samples, as described below, showed that the MR zeolite structure was retained after the high-temperature treatments.

2.2. Catalyst characterization

The chemical composition (including the concentration of Fe) of the catalysts was determined by atomic absorption spectrometry (AAS; Shimadzu, AA6300). Catalysts were characterized by X-ray diffraction (XRD) using a computerized Rigaku D/max-RB diffractometer (Japan, Cu Kα radiation, 0.154056 nm). Scans were taken from 2θ = 10° to 2θ = 90° at a speed of 4°/min. The accelerating voltage and the applied current were 40 kV and 300 mA, respectively.

The nitrogen adsorption-desorption isotherms were obtained at –196 °C on a Quantasorb-18 automatic instrument (Quanta Chrome Instrument Co.). Prior to measurements, samples were evacuated at 300 °C for 10 h. Specific areas were computed from the sorption isotherms using the Brunauer-Emmet-Teller (BET) method.

UV-Vis diffuse reflectance spectroscopy (DRS) was conducted on a U-3010 spectrophotometer (Hitachi) equipped with a standard diffuse reflectance unit under ambient conditions. The scanning range was 190–800 nm and the scan rate was 300 nm/min. HZSM-5 was used as a reference material. The measured spectra were converted into Kubelka-Munk functions and deconvoluted into Gaussian sub-bands that could be quantitatively assigned to the different iron species present in the prepared samples.

Fe K-edge X-ray absorption fine structure (XAFS) of the samples was measured on a BL14W1 beamline at the Shanghai Synchrotron Radiation Facility (China). The storage ring was operated at 3.5 GeV with a ring current of 200 mA. A single Si (111) crystal was used to generate a monochromated X-ray beam. The spectra were recorded with sampling steps of 0.5 eV in the X-ray absorption near edge structure (XANES) region and 1–5 eV in the extended X-ray absorption fine structure (EXAFS) region. The Fe K-edge spectra were recorded in fluorescence mode under ambient conditions and the effect of fluorescence saturation was assessed using α-Fe2O3 as a reference. The EXAFS data were extracted from the measured absorption spectra with the XDAP code. The pre-edge was subtracted using a modified Victoreen curve, and the background was subtracted using cubic spline routines. Finally, normalization was performed by dividing the subtracted absorption spectra by the intensity of the absorption spectrum at 50 eV above the Fe K-edge. Structural information was determined by multi-shell fitting in R space [28]. The fits were assessed by k3 and k4 weighting. Errors were estimated at ±10% for the coordination numbers (N), ±1% for the coordination distances (R), ±5% for the Debye–Waller factor (σ2), and ±10% for the inner-potential correction (E0).

2.3. Steady-state studies

Activity measurements were carried out in a fixed-bed quartz flow reactor (internal diameter, 4 mm), containing ~50 mg catalyst (particle size, 125–200 μm) in all experiments. The reactor was heated by a temperature-controlled furnace. A thermocouple was placed on the external surface of the reactor tube. A N2 (0.15 vol%) reaction mixture was introduced into the reactor at a gas hourly space velocity (GHSV) of 35 000 h⁻¹. Analysis of the reaction products was carried out by gas chromatography (Agilent 6890N equipped with Porapak Q for the analysis of N2O and CO2, and molecular sieve 5A columns for the analysis of N2, O2, and NO). The reaction system was maintained at the selected reaction temperature for 1 h to reach
steady state prior to product analysis. In all tests, N₂ and O₂ were the only gaseous products observed.

The apparent activation energy \( E_a \) and the turnover frequency (TOF) were calculated \([26]\) from the following equations:

\[
E_a = \frac{d(\ln k)}{d(1/T)} \tag{1}
\]

\[
\text{TOF} = \frac{k_p \alpha}{n_n} \tag{2}
\]

where \( k \) is the first-order rate constant and \( n_n \) is the number of active iron obtained from the O₂-temperature-programmed desorption \((\text{O₂-TPD})\) studies, as described in section 2.4.

2.4. O₂-TPD studies

The O₂-TPD experiments were performed under a He \((50 \text{ cm}^3/\text{min})\) flow over 300 mg catalyst and a heating rate of 30 °C/min. Prior to the experiment, the catalysts were pretreated under a flow of 2% N₂O/Ar for 1 h, followed by cooling to 150 °C under the same flow. The adsorbed oxygen species remained on the surface after N₂O decomposition over the catalyst, and were detected using a mass spectrometer \(\text{Hiden}\).

2.5. Pulse-response studies

For the N₂O pulse-response experiments, a six-port switching valve was installed in front of the reactor to periodically change between 2 vol% N₂O/He and pure He atmospheres. Prior to the experiment, the decomposition of N₂O over the catalyst was maintained at 500 °C for 1 h to reach steady state. The periodical switching between 2% N₂O/He and pure He was performed at intervals of 4 min. A similar procedure was adopted in the air pulse-response experiments to compare the diffusion rate of N₂ with that of O₂ in the catalyst bed.

3. Results and discussion

3.1. Steady-state N₂O decomposition

Figure 1 shows the steady-state conversions of N₂O as a function of temperature over the original and thermally treated Fe/ZSM-5 catalysts. As observed, thermal treatment significantly improved the activity of Fe/ZSM-5 catalysts. Among the prepared catalysts, FZ750, treated at 750 °C, achieved 100% N₂O conversion at the lowest reaction temperature studied. Thus, 750 °C was regarded as the optimal treatment temperature. FZ850 featured considerably higher activity than FZ800 and FZ750 in the low-temperature reaction region, whereas FZ750 exhibited the best activity for N₂O decomposition in the high-temperature reaction region. This suggests the occurrence of complex transformations in the active species structure during the thermal treatment process.

3.2. N₂ adsorption-desorption studies

N₂ adsorption was performed to investigate the textural properties of HZSM-5 and Fe/ZSM-5 catalysts. The N₂ adsorption-desorption isotherms exhibited high N₂ uptake at low relative pressures and a plateau at high relative pressures \(\text{Fig. 2}.\). The isotherms were classified as Type I according to IUPAC classification for microporous materials \([29]\) that is typical of HZSM-5, as investigated in a previous research study \([20]\). The surface area and total pore volume of the original and thermally treated Fe/ZSM-5 catalysts were calculated from the corresponding N₂ adsorption-desorption isotherms, and are listed in Table 1. Upon Fe species exchange with protons, N₂ uptake of the non-calcined Fe/ZSM-5 sample decreased \(\text{Fig. 2}.\). Accordingly, the surface area and total pore volume of non-calcined Fe/ZSM-5 decreased \(\text{Table 1}\). It was likely that some Fe oxide species incorporated into the zeolite channel during the ion-exchange process, thus reducing N₂ uptake on non-calcined

Table 1: Textural properties of HZSM-5, and non-calcined and thermally treated Fe/ZSM-5 catalysts.
Fe/ZSM-5 [19]. Treatment temperatures below 750 °C insti-
gated partial migration of small Fe species from the micropore
to the external surface of the zeolite, thereby increasing the
catalyst pore volume. In contrast, treatment temperatures
above 750 °C resulted in the aggregation of FeO₃ clusters and
collapse of the ZSM-5 zeolite framework, subsequently blocking
the channels in FZ800, FZ850, and FZ900 that was responsible
for the low total pore volume and surface area [19].

3.3. XRD analysis

The XRD patterns of HZSM-5 and thermally treated
Fe/ZSM-5 catalysts are shown in Fig. 3. All catalysts displayed
highly crystalline ZSM-5 features, as indicated by the strong
intensity of the characteristic peaks and the weak background
noise in the XRD patterns. These results suggest that the dif-
f erent treatment temperatures employed did not degrade the
crystalline structure of the ZSM-5 zeolite.

Hensen et al. [19] reported that severe calcination condi-
tions could induce growth and ordering of the Fe oxide aggrega-
tes in Fe/ZSM-5, as prepared by chemical vapor deposition of
FeCl₃. As observed in Fig. 3, distinct hematite peaks were not
observed in FZ600 and FZ700, indicating that the Fe oxides on
the catalysts were mainly amorphous. Crystalline FeO₃ was
observed in catalysts FZ750, FZ800, FZ850, and FZ900. To fur-
ther assess the distribution of the FeOx species, the following
experiments were conducted.

3.4. UV-Vis DRS studies

The nature and distribution of the Fe species on the cata-
lysts were investigated by UV-Vis DRS spectroscopy. The ob-
tained spectra were converted into Kubelka-Munk functions
and assigned to Fe⁺↔O charge-transfer bands, as shown in Fig.
4. Bands between 190 and 305 nm were attributed to isolated
Fe²⁺ species (Feo), which are tetrahedrally coordinated within
the zeolite framework (band below 250 nm) and with higher
coordination (band within 244–305 nm). Octahedral Fe in
small oligonuclear Fe oxide species generated bands between
305 and 400 nm (Feo). Bands above 400 nm were attributed to
characteristic asymmetric peaks of large Fe oxide particles.
Bands between 400 and 500 nm were attributed to polymeric
Fe oxide (Fe₃) and bands above 500 nm were characteristic of
large Fe oxide particles without N₂O decomposition activity
[19,23,30]. Based on the work of Pérez-Ramírez et al. [23,30], a
semiquantitative estimation of the distribution of the Fe spe-
cies in the zeolite was performed by deconvoluting spectra into
Gaussian sub-bands, as shown in Table 2 and Fig. 5.

Most of the Fe species in non-calcined Fe/ZSM-5 were octa-
hedral Fe⁺ and oligonuclear Fe oxide [30], most probably de-
ferred from the ion-exchange process (Fig. 4). In contrast, bulk
Fe oxide species were observed in the high-temperature-
treated catalysts as evidenced by the band at ~400 nm. It is
interesting to note that the intensity of bands between 400 and
500 nm (I₃) initially increased and then decreased with in-
creasing treatment temperatures (Table 2). As previously men-
tioned, Fe oxide aggregates on the external surface during
high-temperature treatments [19,24,27]. Based on the XRD
results, the presence of the inflexion points was due to several
reasons: thermal treatment below 750 °C promoted the aggre-
gation of amorphous Fe oxide; the transformation of FeOx spe-
cies from the amorphous to the crystalline state within the
750–850 °C treatment resulted in a reduced volume of FeOx
particles; and the aggregation of crystalline Fe oxide particles
increased I₂ observed for FZ900. The current findings sug-
gested that thermal treatment likely instigated aggregation in both

oxide species. ²Polymeric Fe oxide species.
the amorphous and crystalline Fe oxides. The trend observed for $I_3$ that was in accordance with catalyst activity suggested that the polynuclear Fe oxide species, among all Fe oxide species identified, were the most active towards $\text{N}_2\text{O}$ decomposition.

3.5. XAFS studies

The original and thermally treated Fe/ZSM-5 catalysts, and Fe$_2$O$_3$, FeO, and Fe foil reference compounds were thoroughly examined by XAFS, including XANES and EXAFS. XANES is a fingerprint technique that allows identification of the oxidation state and coordination environment provided availability of a suitable model compound [25,31]. The normalized Fe K-edge XANES profiles are shown in Fig. 6(a). The absence of a pre-edge absorption was due to the forbidden $1s \rightarrow 3d$ transition in octahedral coordinations [19]. The weak peak at $\sim 7140$ eV, corresponding to $1s \rightarrow 4p_z$ transition, suggests that only the distorted octahedral symmetry of the oxide of Fe$^{3+}$ was present in the samples [19]. Fig. 6(b) shows the first derivative of the Fe K-edge XANES profiles of the original and thermally treated Fe/ZSM-5 catalysts, and Fe$_2$O$_3$, FeO, and Fe foil. The similarity

between the spectra of the Fe/ZSM-5 catalysts and Fe2O3 indicates that the Fe species in the Fe/ZSM-5 catalysts are not reduced during thermal treatment in Ar.

Fe K-edge EXAFS analysis provides information on the structural environment of the Fe species in the original and thermally treated Fe/ZSM-5 catalysts [31]. Fig. 7 shows the k3-weighted Fourier transforms of EXAFS oscillations into R space. The spectra of the original and thermally treated Fe/ZSM-5 catalysts were obviously and significantly different from each other, including their peak position and intensity. In R space, an asymmetric peak was apparent at ~0.16 nm, which was attributed to the six oxygen atoms in the first Fe–O coordination shell [31]. The contribution at 0.25 nm was ascribed to considerable scatter and fitted with the Fe–Fe shell. Multi-shell analysis of the EXAFS data was performed using the models proposed by Battiston et al. [31]. The Fe–O and Fe–Fe references were calibrated for the EXAFS data obtained from hematite Fe2O3 by fitting in R space (see Table 3). In particular, the first oxygen-coordination shell was fitted at two different distances, 0.191 nm (Fe–O), and 0.20 nm (Fe–O). However, during the curve fitting process, the number of oxygen atoms in the first coordination shell was not always fitted to six, suggesting the existence of Fe–OH [31]. The second coordination shell can be fitted with two Fe–Fe. The fitting results are listed in Table 3. For ease of comparison between the experimental data and curve fitting results, the Fourier transforms of k3-weighted EXAFS oscillations and the corresponding fitting curves are presented in Fig. 8.

Table 4 shows that thermal treatment greatly influenced the coordination number and slightly changed the bond lengths of Fe–O and Fe–Fe. Thermal treatment induced agglomeration and ordering of iron oxide, as reflected by the increasing Fe–Fe coordination numbers. The Fe–O bond coordination number showed a similar changing trend to that related to the catalysis...
activity with increasing thermal treatment temperatures, indicating that (Fe–O)₂ was the active species for this reaction.

3.6. Pulse-response experiment

The catalytic N₂O decomposition reaction involves the adsorption of N₂O at the active catalytic site followed by decomposition, resulting in the formation of N₂ and surface oxygen. The surface oxygen can be desorbed upon reaction with another oxygen atom or another N₂O. The four steps are shown in the following Eqs.:

\[ \text{N}_2\text{O} + \ast \leftrightarrow \text{N}_2\text{O}^\ast \]  \hspace{1cm} (3)
\[ \text{N}_2\text{O} + \ast \rightarrow \text{N}_2 + \text{O}^\ast \] \hspace{1cm} (4)
\[ \text{N}_2\text{O}^\ast + \text{O}^\ast \rightarrow \text{N}_2 + \text{O}_2 + 2\ast \] \hspace{1cm} (5)
\[ \text{O}^\ast + \text{O}^\ast \rightarrow \text{O}_2 + 2\ast \] \hspace{1cm} (6)

The rate of O₂ desorption is known to influence the activity of the catalyst [18]. The rate-limiting step is either that shown in Eq. (5) or in Eq. (6) depending on the catalyst.

In this study, the characterization and activity tests demonstrated that the long bond length (Fe–O)₂ in the Fe oxide particles was likely advantageous to the activity of the catalysts. To examine the relationship between the intrinsic mechanism of N₂O decomposition and the role of (Fe–O)₂ in Fe oxides, pulse-response and O₂-TPD experiments were conducted.

N₂O decomposition is initiated upon activation of N₂O on the active site, leading to adsorbed O species (α-O), Eq. (4). Two different mechanisms are postulated for the regeneration of the active site: reaction between another N₂O molecule and the oxidized site, Eq. (5), and the recombination of adsorbed oxygen atoms, Eq. (6). To discriminate between these two alternative reactions pathways, pulse-response experiments were performed by pulsing either N₂O or air.

Fig. 9(a) shows the response of the N₂O pulse over catalyst FZ750. Other samples showed similar behaviors to FZ750. As clearly observed, the evolution of molecular oxygen was delayed when compared with that of N₂ as shown in Fig. 9(b). N₂ and O₂ evolved at the same time in the air pulse study, indicating the absence of different diffusion rates of N₂ and O₂ in the bed of catalysts. These results demonstrate that the generated rate of diffusion of O₂ is lower than that of N₂ in N₂O decomposition. According to Sun et al. [15], the recombination of adsorbed oxygen atoms, Eq. (6), is the limiting step of the catalytic N₂O decomposition process.

3.7. O₂-TPD experiment

Fig. 10 shows the O₂-TPD profiles of the thermally treated Fe/ZSM-5 catalysts after exposure to 2% N₂O at 485 °C.

![Fig. 9. Pulse-response profiles obtained by periodically switching (a) 2 vol% N₂O or (b) air to He over FZ750 catalyst at 485 °C.](image)

![Fig. 10. O₂-TPD profiles of the thermally treated Fe/ZSM-5 catalysts after exposure to 2% N₂O at 485 °C.](image)
3.8. Discussion

3.8.1. Effect of high-temperature treatment in Ar on FeOx in Fe/ZSM-5

The nature of Fe oxide strongly influenced the catalytic activity of Fe/ZSM-5 towards N₂O decomposition. Based on the XRD data, two different typologies of FeOₓ present in the catalysts were considered: (1) amorphous state and (2) crystalline state. The UV-Vis DRS results showed that aggregation of the two FeOₓ species increased with increasing treatment temperatures. The FeOₓ aggregation phenomenon was in accordance with earlier observations of Fe/ZSM-5 treated under high temperatures [18, 25, 27].

In this study, aggregation of amorphous and crystalline FeOₓ showed different influence on the activity of the thermally treated Fe/ZSM-5 for direct N₂O decomposition. At treatment temperatures below 750 °C, FeOₓ was amorphous. The activity of the catalysts improved with increasing treated temperatures, indicating that aggregation of amorphous FeOₓ improved the activity of the catalysts. Based on the UV-Vis DRS spectra, XAFS, and O₂-TPD results of the thermally treated Fe/ZSM-5 catalyst, the long [Fe-O₂⁻] bond length in the amorphous polynuclear FeOₓ species promoted the activity of catalysts, indicating that (Fe-O₂⁻) was the active species. At treatment temperatures above 750 °C, crystalline FeOₓ in the Fe/ZSM-5 catalysts aggregated with increasing treated temperatures. Although the intrinsic activity of crystalline FeOₓ was higher than that of the amorphous FeOₓ as observed from the TOF data, increasing amounts of active Fe-O bonds were sealed in the bulk of crystalline FeOₓ with increasing treated temperatures, thereby leading to reduced Cₓ values and decreased catalyst activity.

3.8.2. Thermodynamic origin of the enhanced activity of the Fe/ZSM-5 catalysts towards N₂O decomposition

The rate of N₂O decomposition and correlations of thermodynamic parameters are given as follows [18, 26, 32]:

\[ r = k_p \Delta S^{\text{N}_2\text{O}} = A \exp(-E_a/RT) \Delta S^{\text{N}_2\text{O}} \]  
\[ A = \frac{k_T}{h} \exp(\Delta S^{\text{N}_2\text{O}}) \]

where \( r \) is the rate of N₂O consumption, \( k \) is the rate constant, \( k_B \) is the Boltzmann constant (1.38 \times 10^{-23} J/K), \( h \) is the Plank constant (6.626 \times 10^{-34} Js), \( T \) (K) is temperature, \( A \) is the pre-exponential factor, \( E_a \) is the apparent activation energy, \( n \) is the order of reaction, and \( \Delta S^{\text{N}_2\text{O}} \) is the standard molar entropy of activation. The linear relationship between the reaction rate \( r \) and \( N_2O \) partial pressure \( p(N_2O) \) in Fig. 11 indicates that the decomposition of \( N_2O \) over FZ750 catalyst is a first-order reaction. Findings from previous research studies [18, 26] also indicated that \( N_2O \) decomposition is a first-order reaction \( (n = 1) \). Arrhenius plots obtained from the steady-state \( N_2O \) decomposition (below 20% conversion efficiency) over the thermally treated Fe/ZSM-5 catalysts are shown in Fig. 12. Kinetic parameters for the catalysts were calculated from Arrhenius plots under the assumption of first-order disappearance of nitrous oxide, as shown in Table 6. The accuracy of \( E_a \) was ±10 kJ/mol.

From Table 6, the apparent activation energy \( E_a \) and apparent pre-exponential factor \( A \) of the catalysts were substantially different. As seen, \( E_a \) increased from 139 kJ/mol for FZ600 to 209 kJ/mol for FZ750, and then decreased to 105 kJ/mol for FZ900. Simultaneously, \( A \) increased from \( 3.0 \times 10^3 \) to \( 7.9 \times 10^{10} \), and then declined to \( 5.3 \times 10^7 \) Pa⁻¹. The values of \( E_a \) were proportional to lnA values of the catalysts (Fig. 13) that can well be explained by the compensation effect [33]. Based on the steady-state activity of the catalysts towards \( N_2O \) decomposition, \( A \) was a better determining factor than \( E_a \) to the activity of the catalysts. Equation (6) shows that \( \Delta S^{\text{N}_2\text{O}} \) of the various transition state species (e.g., α-O) plays an important role in determining the value of \( A \). Based on these analyses, the standard molar entropy \( \Delta S^{\text{N}_2\text{O}} \) of α-O and the active sites were the major factors influencing the reaction rate.
Table 6
Apparent activation energy ($E_a$) and pre-exponential factor ($A$) for N$_2$O decomposition over the thermally treated Fe/ZSM-5 catalyst.

Fig. 13. Plot of ln A as a function of $E_a$ for N$_2$O decomposition over the thermally treated Fe/ZSM-5 catalysts.

The structure of the active site likely influenced the value of active entropy of the transition state of $\alpha$. When $\alpha$ deviates from the Fe active sites, prior to rupture of the bond (Fe–O)$_2$, the latter donates electron to Fe because the bond energy of (Fe–O)$_2$ species is lower than that of (Fe–O)$_1$ species, thereby confirming the hypothesis that (Fe–O)$_2$ species are the active species.

Based on the value of A, (Fe–O)$_1$ species promoted the activity of the catalysts by increasing the entropy of the transition state of $\alpha$. The higher the amount of active sites on the catalyst, the larger the total value of active entropy. Therefore, FZ750 that possessed the highest amount of (Fe–O)$_2$ had the highest activity towards N$_2$O decomposition.

The polynuclear Fe oxide species facilitate the recombination of adsorbed oxygen atoms in contrast to the oligonuclear Fe oxide species. (Fe–O)$_2$ existed in both the oligonuclear and polynuclear Fe oxide species. However, the higher amount of (Fe–O)$_2$ species in the polynuclear Fe oxide species was beneficial to enhancing the activity of the catalysts. For example, CN of (Fe–O)$_2$ and the content of the oligonuclear Fe oxide species in the original Fe/ZSM-5 catalyst were both high. Moreover, $C_n$ was low. Therefore, the number of (Fe–O)$_2$ in the polynuclear FeO$_x$ species determined the $C_n$ of the catalysts, which was estimated by multiplying CN of (Fe–O)$_2$ by the content of the amorphous polynuclear FeO$_x$ species.

4. Conclusions

The aggregation of FeO$_x$ species on the external framework of ZSM-5 zeolite during thermal treatment played a dominant role in the activity of Fe/ZSM-5 towards N$_2$O decomposition. The optimum treatment temperature was determined as 750 °C. Fe–O with long bond lengths in the polynuclear amorphous FeO$_x$ species was the active species for N$_2$O decomposition. The amount of active FeO$_x$ species was a key factor influencing the apparent activity of the Fe/ZSM-5 catalysts. When compared with the apparent activation energy $E_a$, the apparent pre-exponential factor $A$ was more important in determining the reaction rate, where $A$ depends on the total value of active entropy.

Graphical Abstract

Role of aggregated Fe oxo species in N2O decomposition over Fe/ZSM-5

Bo Zhang, Fudong Liu, Hong He*, Li Xue
Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences

Fe–O species, with a long bond length, in polynuclear amorphous Fe oxo species are the real active species of Fe/ZSM-5 towards N2O decomposition. Apparent pre-exponential factor is important to the reaction rate.
